This research aims to investigate the cycling of carbon and nitrogen through the decomposer and herbivore food webs using stable isotope analysis (δ13C and δ15N) and to determine how fire affects food web structure and ecosystem functioning.

**Background**

Low intensity fires are used extensively in the management of Tasmania’s Buttongrass Moorlands, despite being little known about the long term effects of repeated burning on ecosystem functioning. Understanding patterns of species loss and the impacts on ecological functioning are fundamental to predicting the long term effects of fire. In the Buttongrass, invertebrates play key roles in the decomposition and mineralisation of organic matter and the mobilisation of nutrients contributing directly to peat formation. Stable isotope “signatures” can enable us to determine taxon relationships within the food web and make inferences about potential flow on effects from fire induced changes in structure (Fig. 1).

**Methods**

- Plants, and invertebrates were collected from Buttongrass Moorlands representing five different age classes (time since fire).
- Samples represented a wide range of functional groups including decomposers, primary producers, herbivores and predators and identified to species/morphospecies.
- Specimens were oven dried and ground to a fine powder for analysis through the Isotope Ratio Mass Spectrometer (IRMS) to determine natural abundances of δ13C & δ15N.

**Key findings to date**

- Buttongrass moorlands support a diverse invertebrate fauna with almost 6000 individuals from 24 orders collected.
- Greater than 25% were spiders (Fig. 2).
- Recently burnt sites supported significantly more Arachnids, Coleopterans and Hymenopterans than long unburnt sites.
- Preliminary results to date show a decrease in δ13C but no change in δ15N with time since fire for many taxa (Fig. 3).

**Implications and future direction**

Further analyses of δ13C and δ15N from representative invertebrate and plant taxa will be used to trace the flow of nutrients through the ecosystem and determine the impact of fire on food web structure and predict the stability of ecosystem processes and nutrient cycling.
